Abstract

Different lanthanides (Y, Ce) ions doped anatase TiO$_2$ nanosheets films with dominant high-reactivity [001] facets were synthesized on transparent conductive FTO substrates via a simple, one-step solvothermal method. In the present work, the amounts of HF and the doping ratios of rare earths were explored in detail. The crystal morphologies, structural features, binding information, optical absorption, and photocatalytic performances were investigated systematically. The optimal conditions of HF amount and rare earths doping ratios proved to be 2 mL and 1.0%, respectively. The results showed that the optimum lanthanides (Y, Ce) doped anatase TiO$_2$ nanosheets films displayed higher photocatalytic activities than pure TiO$_2$ films, and Y doped TiO$_2$ showed better photocatalytic activity than Ce doped TiO$_2$. The possible mechanism of the photocatalysis can be mainly ascribed to the synergistic effect of lanthanides doping and exposed high-reactively [001] facets.

Introduction

As a sustainable technology, nanostructure TiO$_2$-based photocatalysis has received much attention in the last few decades because it has potential to use in the fields of energy and the environment, such as dye-sensitized solar cells [1-5], hydrogen production [6, 7] and photocatalytic degradation [8-11], etc. However, some weaknesses still exist in practical utilization of nanostructure TiO$_2$ photocatalyst. TiO$_2$ has a wide band gap of 3.24 eV [12-14], which leads to a low utilization ratio of solar energy. On the other hand, high recombination of electron-hole pairs decreases the photo-quantum efficiency.

To solve these problems, a great number of studies have focused on how to modify TiO$_2$ doped with ions such as noble metals [15, 16], nonmetals [17-19], rare earths (RE) elements [20-22], etc. Among these, the modifying by RE elements has turned out to be a feasible and promising strategy due to the 4f electron configuration of RE elements, which can reduce the electron-hole pair recombination [23-27]. Moreover, the modification by RE elements can increase the photoadsorption of organic substrates on the TiO$_2$ surfaces, which also enhances the photocatalytic performance. For example, Duan et al. [28] prepared praseodymium doped TiO$_2$ (Pr-TiO$_2$), which showed that the
redox activity was influenced by the position of the band edge and the photocatalytic performance was improved by introducing doping rare earth. Meski et al. [25] prepared lanthanum doped TiO$_2$ (La-TiO$_2$). The photocatalytic performance of TiO$_2$ was improved because La shortened the bandwidth of TiO$_2$ and decreased the recombination rate of photo-generated electron-hole pairs.

According to density functional theory [12, 29], the common surface energies of certain anatase facets are 0.9 J/m$^2$ of {001}, 0.53 J/m$^2$ of {100}, 0.44 J/m$^2$ of {101} [30, 31]. Although the theory cannot represent the actuality, the result is still meaningful: {001} facets show a higher reactive activity than {101} facets, and the anatase TiO$_2$ is commonly formed by {101} facets with stable thermodynamic properties due to its low surface energy [32-34]. Since research by Yang et al. [35] in 2008 who successfully synthesized TiO$_2$ with 47% exposed {001} facets, many researchers have been exploring the properties and performances of the {001} facets as well as how to prepare TiO$_2$ with high percentage of exposed {001} facets.

The advantages of rare earth doping and the {001} facets controlling are obvious. However, few studies have been focused on the synergistic effects of both lanthanides ions doped TiO$_2$ nanosheets and the morphological control of expose {001} facets, which may contribute to excellent photocatalytic activity. Here, we investigate the synthesis of lanthanides (Y, Ce)-doped anatase TiO$_2$ nanosheets films with dominant high-reactivity {001} facets on fluorine-doped tin dioxide (FTO), which was proved to be of better stability than Indium tin oxide (ITO) and common glass in HF [36]. In addition, the effects of different doping amounts of REs on the characteristics of TiO$_2$ such as the morphologies, structures, luminescence properties, and the photocatalytic performances are studied systematically.

**Experiment Section**

**Chemicals and Materials**

All reagents used in this study were of the highest available purity, purchased from Chemical Reagent Company of Beijing. Deionized water (18.2 MΩ.cm) obtained from a Direct-Pure Up 10 water system (RephiLe Bioscience, Ltd.) was used through the experiments whenever needed. The FTO substrates used in this study were purchased from Shenzhen CSG Float Glass Co. Ltd (Shenzhen, China).

**Synthesis**

A solvothermal method is used to prepare lanthanides (Y, Ce) doped TiO$_2$ nanosheets films on FTO substrates. The FTO substrates are prepared with sizes of 2.0 × 4.0 cm$^2$, and cleaned ultrasonically by deionized water, acetone, and ethanol for 1 h separately. In most experiments, 40 mL of acetic acid (HAc) is mixed with rare earth nitrate (RE(NO$_3$)$_3$), 10 mL of tetrabutyl titanate (Ti(OBu)$_4$), and appropriate amount of hydrogen fluoride (HF). Every chemical is added with uniform stirring. First, a proper amount of HF are considered to explore the impact of photocatalytic properties. Then, the molar ratios of RE elements and Ti are investigated in the range of 0.25%, 0.5%, 1.0%, 1.5%, and 2.0%, respectively. The solution is transferred into a 100 mL Teflon-lined autoclave, and the FTO substrate is on the bottom of the autoclave with the conductive surface facing upward. The solution is kept at 200 °C for 12 h. Having finished the reaction, the FTO substrates with RE-TiO$_2$ films are pick out and washed with ethanol several times, then dried at 60 °C for 24 h. Finally, all the RE-TiO$_2$ films are calcined at 500 °C for 6 h with a rate of 1 °C/min.

**Characterization**

The crystal structure is examined by X-ray diffraction (XRD) analysis with a Bruker axs D8 Advance using Cu Ka
radiation (Bruker, Germany). The morphology of the samples is examined by TEM-2100F high-resolution transmission electron microscopy (TEM) (JEOL, Japan) and SU-8020 field-emission scanning electron microscopy (SEM) (Hitachi, Japan). The diffuse reflectance spectra (DRS) are characterized by an UV-vis spectrophotometer (UV 2550, Shimadzu, Japan). X-ray photoelectron spectroscopy (XPS) data are obtained with an ESCALab220i-XL electron spectrometer from VG Scientific using 300 W Al KR radiation ($E = 1486.6$ eV) in a base pressure of $3 \times 10^{-9}$ m bar. The binding energies are referenced to the C 1s line at 284.8 eV from adventitious carbon. The photoluminescence (PL) spectra are tested with a Japan Hitachi F7000 fluorescence spectrophotometer using a 330 nm line from a xenon lamp.

**Evaluation of Photocatalytic Properties**

The photocatalytic properties of the samples are compared by analyzing the degradation rates of Methylene Blue (MB) and Methyl Orange (MO). All of the RE-TiO$_2$ films of 2.0 cm $\times$ 4.0 cm are used. Before being tested, all of the samples are immersed in a sodium hydroxide (NaOH) solution (5 mol/L, 50 mL) for 1 h, washed with deionized water several times, and then dried. To establish the adsorption-desorption equilibrium, samples are submerged in organic solution (MB/MO, 10 mL, 10 mg/L) in 60 mm culture dishes separately for 12 h. In the experiment, a 30 W UV lamp with a maximum emission at approximately 365 nm was used as the illumination source. And the absorption of organic solutions (MB/MO, 10 mL, 10 mg/L) are measured every 1 h by the ultraviolet spectrophotometer. The data are analyzed by recording the absorption peaks of MB at 664 nm and MO at 465 nm.

**Results and Discussion**

HF, with the strong corrosion ability, is usually employed as capping agent in experiments. Our initial research focused on identifying a proper amount of HF to obtain TiO$_2$ with high active reactive [001] facets. Here, pure TiO$_2$ is used to study the impact of HF on the [001] faces by regulating the addition of HF amounts in the range of 0 mL, 1 mL, 2 mL and 3 mL. Figure 1 shows the SEM images in different HF amounts, and the simulated shapes are showed in Figure SI-1 [30, 37]. As can be seen in Figure 1(a), the nanoparticles show an integral bipyramidal structure, and the isosceles triangular sidewalls are the [101] facets. In Figure 1(b), the bipyramid are partly eroded. The isosceles trapezoidal sidewalls are the [101] facets, and the flat squares are the [001] facets. In Figure 1(c), the nanoparticles are further eroded into flakes. As is shown in Figure 1(d), there are some nanopores in every flake. The erosion of TiO$_2$ nanosheets are increased with the increase of HF concentration. Definitely, HF can selectively erode [001] facets because titanium and oxygen on the surface of the [001] and [101] facets have different geometric arrangement. At high concentration, HF selectively etches [001] facets by the -OH replacement and -TiO$_2$ dissolution on the surface of [001] facets [38]. According to the above results, the samples have the highest percentage of exposed [001] facets at 2 mL of the HF addition. As a result, 2 mL of HF is used for all subsequent experiments.

The crystalline phases of synthesized pure and doped TiO$_2$ are examined by XRD. As shown in Figure 2, the intensity peaks of all samples are consistent with the crystal structure of tetragonal-anatase TiO$_2$ with $I4_1/amd$ space group symmetry (JCPDS No. 21-1272) [39, 40], indicating that the high crystallinity of these products [41] (Figure 2a). However, we notice that no other crystalline phases (such as Y$_2$O$_3$, CeO$_2$ or CeO$_3$) are observed, which suggest that rare earth ions might be well dispersed on the surface of TiO$_2$. It can be observed that the main diffraction peaks (101) have a negligible shift to high degrees after rare earth ions doping compared with pure TiO$_2$ nanosheets, as shows local amplification (Figure 2(b)). It is suggested that there are small contortions in the TiO$_2$ lattices [42]. Actually, the ionic radii of rare earth elements are much larger than Ti$^{4+}$ ($Y^{3+}$, Ce$^{3+}$, Ce$^{4+}$ and Ti$^{4+}$ are...
101.9 pm [43], 98 pm, 114 pm [44] and 60.5 pm [43], respectively), which make it difficult for rare earth ions to enter into the TiO$_2$ lattice. Thus, the small contortions in the TiO$_2$ lattices may due that some rare earth ions present on the grain boundaries [45] or replace Ti$^{4+}$ on the surface.

TEM is employed to characterize the crystallographic structures of the RE-TiO$_2$ nanosheets and pure TiO$_2$ nanosheets samples, as shown in Figure 3. Figure 3(a-c) shows that all the pure and doped TiO$_2$ samples have uniform layer-structured sheets structures. The high-resolution TEM image of the sheet structure lying on the TEM
grid suggest that the lattice spacing parallel was 0.19 nm, in good agreement with the spacing of the (200) and (020) lattice planes of the TiO$_2$ (Figure 3(g)) [46]. The diffraction spots in selected area electron diffraction (SAED) patterns (Figure 3(d)) are measured, resulting in corresponding to the facets of (200) and (020) facets, which means that the top and bottom facets observed are both [001] facets. The HRTEM images of RE-TiO$_2$ nanosheets (Figure 3(h-i)) directly reveal that the lattice spacing parallel is 0.235 nm, indicating that the top and bottom facets of the RE-TiO$_2$ nanosheets are the {001} facets [47]. Moreover, the corresponding SAED pattern (Figure 3(e-f)) can be indexed into the diffraction spots of the [001] zone, which also confirm that the faceted surface of RE-TiO$_2$ nanosheets is the (001) surface.

Figure 4 shows SEM images of pure and doped TiO$_2$ nanosheets samples. As illustrated, all of pure and doped TiO$_2$ nanosheets samples show well-defined nanosheets morphological structures with two exposed {001} facets in agreement with TEM results and the growth of most nanosheets are perpendicular to the substrate. The typical crystal type of TiO$_2$ belongs to the tetragonal system. The thickness of RE-TiO$_2$ is in the range of 0.14 - 0.4 μm, the sample length is 1.7 - 3.5 μm, and the length on the plane of fracture is 0.9 - 2.8 μm. However, the thickness of pure TiO$_2$ is 0.6 μm. Obviously, doping with rare earth elements cannot change the crystal structures according to the XRD results, but can decrease the thickness of TiO$_2$. The relative sizes of as-prepared TiO$_2$ are measured according to the SEM images, as shown in Table S1-1. The percentage of the {001} facets is calculated by the measured sizes (shown in Figure S1-1(d)). As is shown in Table 1, the percentage of the {001} facets exceed 80% at 1.0% RE-TiO$_2$,
among which the percentages of the [001] facets at 1.0% Y-TiO$_2$ and 1.0% Ce-TiO$_2$ are 91% and 92%, respectively. It can be seen that the percentage of the [001] facets has a trend of increasing with the adding of RE nitrates because RE ions can accelerate the anisotropic platelet growths of TiO$_2$ crystallites [13]. However, the percentage of [001] facets decreases at higher doping levels in the range of 1.0-2.0%, which can be ascribed to the introduction of too much nitrate ions (NO$_3^-$). It has been reported that nitrate ions (NO$_3^-$) can adsorb onto the surface of the nucleus and reduce the adsorption capacity of the fluoride ions, and thus decreasing the percentage of the [001] facets [48].

Doping has a significant effect on adjusting the number of active group and combination ratios of electron-hole pairs. To confirm the element compounds and the valence states of elements, the as-prepared anatase RE-TiO₂ nanosheets films were investigated by XPS (Figure 5). As shown in Figure 5(a), the Ti 2p peaks of pure TiO₂ are present at 458.8 eV (Ti 2p₃/₂) and 464.5 eV (Ti 2p₁/₂). The difference value of 5.7 eV between the two bands suggests that Ti exists in the Ti⁺⁺ state [49]. The peaks of two kinds of 1.0% RE-TiO₂ are all shifted to higher binding energy compared with pure TiO₂, which is likely due to the orbits hybridization of rare earth cations and O anion [50, 51]. Moreover, the increasing ionic banding energy results from charge transfer between occupied O 2p and empty RE 3d orbitals [52], which likely results in narrower banding gap. The O 1s spectrum is shown in Figure 5(b). The peak of pure TiO₂ at 529.7 eV matches with the lattice O atoms, and the peak at 531.7 eV matches with the surface hydroxide groups, nearly corresponding with the literature [24]. The hydroxyl groups can trap holes, which inhibits the combination of electron-hole pairs, resulting in the enhancement of photocatalytic performance. In Figure 5(c), the peaks at 159.9 eV and 158.1 eV correspond to Y 3d₃/₂ and Y 3d₅/₂, which means that Y exists as yttrium oxide (Y₂O₃), in agreement with the literature [21]. The combinations of Y and O can create more oxygen vacancies, which delay the combination of photo-generated electron-hole pairs, [53]. In Figure 5(d), four peaks are present in the Ce 3d spectrum, and two peaks (p1 and p3) are in agreement with the Ce 3d₃/₂ spin-orbit state. The two peaks (p2 and p4) are in agreement with the Ce 3d₅/₂ spin-orbit state, which means that Ce⁺³/Ce⁺⁴ exist at the same time [54]. The existence of Ce⁺³ (p1 and p3) means that a portion of the Ce ions exists as cerium oxide (CeO₂). The other Ce⁺⁴ ions are oxidized to become Ce⁺⁵⁺, which suggests that Ce ions can form more oxygen vacancies [27, 55]. In summary, the XPS spectrum illustrates that rare earth ions are definitely doped into the TiO₂.

The UV-vis DRS spectra plays a crucial role in detecting the optical properties and confirming whether the rare earth elements are doped in TiO₂. In Figure 6, the band gap of TiO₂ is 3.29 eV, which is close to the value of 3.24 eV in the literature [56]. The band gaps of RE-TiO₂ samples are decreased, which means the absorption band is moved
to the visible region slightly. The red shift indicates that the doping of the rare earth ions can expand the response range of the spectrum to the visible region. Figure 6(b) is the local amplification of a region in Figure 6(a). The different band gaps in Figure 6(b) illustrates that Y-TiO$_2$ (3.17 eV) has a narrower band gap than Ce-TiO$_2$ (3.25 eV), resulting from different doping levels.

FIG. 6 UV-VIS DRS SPECTRA OF PURE TiO$_2$ FILMS AND 1.0% RE-TiO$_2$ FILMS. (A) INTEGRAL DRS SPECTRA AND (B) SECTIONAL DRS SPECTRA

It has been known that TiO$_2$ modification with lanthanides ions yield excellent electrons scavenging capacity and increase separation efficiency of electron-hole pairs [19]. Thus, we used the PL technique to measure the separation capacity of photo-generated electrons and holes of pure and RE-TiO$_2$ nanosheets films. Figure 7 shows the PL spectra of pure and RE-TiO$_2$ nanosheets films. Compared with the pure TiO$_2$, the RE-TiO$_2$ samples exhibit lower intensity of emission spectrum, which clearly indicates that a more efficient transfer and separation of electrons and holes caused by doped RE ions. However, the results also show that Y-doped TiO$_2$ has the lower intensity of emission spectrum than Ce-doped TiO$_2$.

![Figure 7 PL Spectra of Pure TiO$_2$ and RE-TiO$_2$ Samples](image)

FIG. 7 PL SPECTRA OF PURE TiO$_2$ AND RE-TiO$_2$ SAMPLES
It is widely accepted that organic dyes can severely contaminate the environment. MB and MO are the representative of organic dyes. As a result, they are usually chosen as a metric for photocatalytic performance. Blank samples (organic solution without catalyst samples under irradiation) are also tested for comparison to avoid the influence of the dye sensitization. The degradation ratios equals to \(\frac{C_t}{C_0}\) (\(C_0\) and \(C_t\) represent the initial concentration of dyes and the concentration at time \(t\)). The reaction rate constant named symbol \(\kappa\) equals to \([\ln(\frac{C_t}{C_0})]/t\) [57], which representing as the speed of degradation.

Figure 8a summarizes the photocatalytic performance of TiO\(_2\) doped with 1.0% rare earth under UV light irradiation by degrading the MB solution. The degradation rate of the blank MB solution under UV light irradiation is approximately 30%. On the other hand, the photocatalytic activity is apparently improved when the Y-TiO\(_2\) are dipped in MB solution. It is obvious that the photocatalytic performance of the TiO\(_2\) films doped with rare earth has been improved compared to pure TiO\(_2\) films. In Figure S1-2a, it is observed that the photocatalytic performance increases when the doping molar ratio is less than 1.0% and has a contrasting trend of decreasing from 1.0 - 2.0%. This means that the optimal doping amount is 1.0%, which is to say that the Y-TiO\(_2\) films have higher photocatalytic performance than other molar ratios under 2.0%. When the molar ratio of Y/Ti reaches 1.0%, the degradation rate is highest in this experiment. Generally, the reaction rate of degrading organic dyes actually corresponds to photo-generated \(\cdot OH\) radicals decomposing organic dyes. The reaction rate constant is the highest in Y-TiO\(_2\) films, as shown in Figure S1-2b, which approximately equals 7.01×10\(^{-3}\) min\(^{-1}\) (Table 2).
To ensure the effect on the photocatalytic activity, an expanded experiment involving the degradation of MO solution is measured under UV light irradiation. The summary of the photocatalytic performance of the TiO$_2$ samples is shown in Figure 8c and Figure 8d. The reaction rate constant of pure TiO$_2$ and Y-TiO$_2$ (shown in Figure SI-2(c-d)) are 3.75×10$^{-3}$ min$^{-1}$ and 6.28×10$^{-5}$ min$^{-1}$, which suggest that the reaction rate constant of Y-TiO$_2$ is about two times faster than the value for pure TiO$_2$ nanosheets samples. It is clear that superior photocatalytic performance is related to appropriate amounts of doping, low bandgap energy, a high percentage of exposed high-activity {001} facets, and a high density of nanosheets. The photocatalysis results show that TiO$_2$ nanosheets films doped with rare earth elements can optimize the photocatalytic activity compared to pure TiO$_2$ nanosheets films.

The photocatalytic activities of Ce-TiO$_2$ (Figure SI-3) have similar trends compared with Y-TiO$_2$. However, Y-TiO$_2$ have better photocatalytic performances than Ce-TiO$_2$, and RE-TiO$_2$ have better photocatalytic performances than pure TiO$_2$. In the degradation of MB and MO solution, the degradation rate of 1.0% Y-TiO$_2$ reaches 88.5% and 85.2% after 5 h, the degradation rate of 1.0% Ce-TiO$_2$ reaches 83.0% and 82.8% after 6 h as well, and both of them have surpassed the pure TiO$_2$ of 20%, the degradation rate of pure TiO$_2$ is only 60%.

![FIG. 9 PHOTOCATALYTIC PROCESSES ON RE-TiO$_2$ SURFACE UNDER UV-LIGHT IRRADIATION](image)

Base on the photocatalytic experiment results, the enhanced photocatalytic activities of lanthanides (Y, Ce) doped anatase TiO$_2$ nanosheets films can be mainly resulted from the synergistic effects of lanthanides doping and exposed high-reactively {001} facets. (Figure 9) Lanthanides ions yield excellent electrons scavenging capacity and
increase separation efficiency of photo-generated electron-hole pairs. When lanthanides ions are doped onto the crystal surface or into lattices, the lattices are distorted and the charges lose balance [58]. To redress this imbalance, oxygen vacancies are formed in the vicinity, which can act as the active center of the reaction to inhibit the recombination of charge carriers. Therefore, these lanthanides (Y, Ce) ions, as impurities, form active trapping centers to trap photoelectron, which contributes to reactions with adsorbed O2 and form highly reactive superoxide ions (·O2-) [59]. Superoxide ions (·O2-) can strongly reactive with organic molecules. Furthermore, doping with rare earth elements caused a red shift in photo-response, which can increase more photons were absorbed by samples. The results of the UV-vis DRS spectra confirmed that the band gaps of the doped TiO2 samples are reduced.

Conclusion

Different lanthanides (Y, Ce) ions doped anatase TiO2 nanosheets films with dominant high-reactivity {001} facets have been synthesized on FTO substrates via a simple, one-step solvothermal method. Compared to the pure TiO2 films, Lanthanides (Y, Ce) ions doped TiO2 nanosheets films showed better photocatalytic efficiency. The degradation rate of 1.0% RE-TiO2 reaches over 80%, both of which have surpassed the pure TiO2 of 20%. The as-prepared TiO2 films reveal that different photocatalytic properties result from different concentration of solutions with different types of rare earth elements. 2 mL of HF and 1.0 mol% of RE-TiO2 are the most appropriate amount.

RE-TiO2 don’t have any obvious differences in mechanism. Therefore, the results can be the theoretical support for the modified TiO2 co-doped by yttrium and cerium, which can set as raw material to avoid further separation from primary ore or the original waste tricolor phosphors. We hope that this study would provide a new route for the modification of TiO2 materials and offer methods for environmental management and energy proposal.
