Low-Cost Y-Doped TiO$_2$ Nanosheets Film with Highly Reactive {001} Facets from CRT Waste and Enhanced Photocatalytic Removal of Cr(VI) and Methyl Orange

Qijun Zhang,*† Yu Fu,† Yufeng Wu,*† Yi-Nan Zhang‡ and Tieyong Zuo†

Abstract: In this paper, efficiency recovery of rare earth elements from cathode ray tubes (CRT) waste. Moreover, recycled yttrium was also served as raw material to produce a low-cost Y-doped TiO$_2$ nanosheets film with exposed {001} facets. An etching/dissolution growth mechanism was postulated by systematically investigating the influence of the reaction time. The synergistic effect of the Y dopant and the dominant {001} facets endows TiO$_2$ nanosheets film with excellent activity in the photoremoval of Methyl Orange (MO) and Cr(VI). A possible mechanism of photoremoval of MO and Cr(VI) is proposed. This study not only contributes to recycling methods for CRT waste but also presents a new way to prepare low-cost sustainable photocatalytic materials using economically viable waste.

Keywords: CRT waste, Recycling, Rare earth elements, Y-doped, TiO$_2$ nanosheets, {001} facets, Photocatalytic activities

**INTRODUCTION**

Nanophase anatase titanium dioxide (TiO$_2$), as the most promising semiconductor photocatalyst for a variety of solar-driven clean energy and environmental pollution treatment technologies, has been widely studied owing to its low cost, resistance to photocorrosion, biological and chemical inertness, and strong oxidizing properties.1−3 However, practical applications of TiO$_2$ nanoparticles as a photocatalyst are greatly restricted by the low quantum yield caused by the high electron−hole pair recombination rate and the difficulty of separating the suspended nanoparticles from aqueous solutions for reuse.4−6 To solve these problems, many recent works have attempted to immobilize TiO$_2$ on a solid carrier and/or change the electronic structure of the TiO$_2$ via doping with metallic and nonmetallic elements.4,7−9 Recently, doping with rare-earth elements (REEs) has shown great potential,10,11 because: (1) REEs has a 4f electron configuration, which reduces electron−hole pair recombination; and (2) REEs doping can promote the chemical adsorption of organic substrates on the TiO$_2$ crystal surfaces and improve its photocatalytic efficiency. However, using REEs-doped TiO$_2$ photocatalysis materials in practical applications it is a challenge because the prices for these metals have been generally increasing over the past few years.

Cathode ray tubes (CRT), which contain a considerable amount of rare earth, are a significant component of display devices such as computer monitors and TVs. With the development of the information technology and electronic industry, display devices with CRTs have been replaced by new products such as liquid crystal displays (LCDs) and plasma display panels (PDPs).12,13 As a result, enormous amounts of CRT waste are constantly generated every year worldwide. Generally, an ordinary CRT display unit is composed of approximately 63.2 wt % of screen glass, 24.0 wt % of cone glass, 0.4 wt % of a getter plus an electron gun, 0.4 wt % of ceramic seal and 0.04 wt % of phosphor powders.14 Although the glass, metal and ceramic materials in the CRT are often recycled, the phosphor powders are usually simply discarded or stockpiled, despite their high content of valuable REEs, such as yttrium and europium.15,16 Recovering REEs from CRT phosphor waste is, therefore, interesting and important in terms of both waste treatment and the recovery of economically viable raw materials for low-cost synthesis of photocatalysis materials.

It has been demonstrated that TiO$_2$ catalytic properties, especially its photocatalytic activities, are closely associated with its exposed facets.17 Therefore, increasing research attention is now being directly toward engineering the surface structure of TiO$_2$ at the most fundamental and atomic level, namely the morphological control of the {001} facets in the microscale and nanoscale range to fine-tune its photocatalytic activities.18−21

Exposed {001} Facets from CRT Waste with 89% of {001} facets via the hydrothermal reaction of the resultant Y-doped TiO$_2$ nanosheets waste. First, 50 g of CRT phosphor waste samples was leached with 1 M anatase TiO$_2$ nanosheets exhibited superior photocatalytic activity under UV light irradiation. Moreover, to the best of our knowledge, degradation of Methyl Orange (MO) aqueous solutions under CRT phosphor waste and using recycled yttrium as a dopant to obtain enhanced photocatalytic activities.

This work focuses on recovering yttrium and europium from CRT phosphor waste and using recycled yttrium as a dopant to produce Y-doped TiO$_2$ nanosheets film with exposed highly reactive {001} facets. The chemical, mineralogical and morphological characteristics of the phosphor waste, recycled components and the as-synthesized Y-doped TiO$_2$ nanosheets film were studied. The corresponding photocatalytic activities of the resultant Y-doped TiO$_2$ nanosheets film were evaluated for the photocatalytic reduction of Cr(VI) and the photo-degradation of Methyl Orange (MO) aqueous solutions under UV light irradiation. Moreover, to the best of our knowledge, there are no reports investigating the use of CRT phosphor waste for the preparation of Y-doped TiO$_2$ nanosheets film with dominant {001} facets.

**EXPERIMENTAL SECTION**

**Chemicals and Materials.** The CRT waste was supplied by Shenzhen Green Eco-manufacture Hi-tech Co., Ltd.. The as-received CRT waste was crushing, grinding and dried at 110 °C until a constant weight was achieved. To homogenize the particle size and remove larger impurities such as glass particles and light films with high aluminum contents, the samples were milled using a planetary mill (72 h, 400 rpm) and passed through a 0.074 mm sieve before use. The rest of the reagents were all analytical grade and were purchased from the Chemical Reagent Company of Beijing.

**Proposed Process.** The proposed procedure of the anatase Y-doped TiO$_2$ nanosheets film with exposed {001} facets from CRT waste is divided into the following stages: (a) leaching and separation of REEs, (b) recycling of Y and Eu, and (c) synthesis of Y-doped TiO$_2$ nanosheets film, as shown in Scheme 1.

**Leaching and Separation of REEs.** A traditional wet metallurgy procedure was used to leach and separate REEs from CRT phosphor waste. First, 50 g of CRT phosphor waste samples was leached with 1 L, 3 M sulfuric acid and 5 mL of H$_2$O$_2$ at 50 °C for 2 h with stirring (300 rpm). Then, the resulting solutions were filtered to produce Y–Eu sulfate solutions. Finally, the Y–Eu sulfate solutions were separated and purified by traditional ammonia precipitation, oxalate precipitation and calcination, and Y$_2$O$_3$/Eu$_2$O$_3$ mixtures were obtained.

Recycling of Y and Eu. Recycling of Y and Eu from the as-obtained Y$_2$O$_3$/Eu$_2$O$_3$ mixtures followed a procedure from the literature with some modifications.

In a typical process, 5 g of as-obtained Y$_2$O$_3$/Eu$_2$O$_3$ mixtures were dissolved in 20 mL of hydrochloric acid (37%), and 50 mM (NH$_4$)$_2$SO$_4$ was added to achieve a sulfate:europium molar ratio of 7:1. Next, the pH was altered to 3.9 by adding drops of ammonia, 20 vol % of an isopropyl alcohol scavenger was added, and the solution was illuminated with 25 W UV Lamp for 72 h. After the photochemical treatment, the solutions were filtered, and Y-containing solutions and EuSO$_4$ were both obtained. Subsequently, the Y-containing solutions were slowly evaporated at 70–80 °C to obtain yttrium sulfate. The as-obtained yttrium sulfate can be used as a raw material to synthesize the Y-doped TiO$_2$ photocatalysis material.

Synthesis of Y-Doped TiO$_2$ Nanosheets Film. Y-doped TiO$_2$ nanosheets film with exposed {001} facets was fabricated by a solvothermal method. In a typical process, 10 mL of tetrabutyl titanate (Ti(OBu)$_4$) was added dropwise into acetic acid (40 mL) and the mixture was ultrasonicated for 15 min (500 W power). Then, appropriate amounts of the recovered Y-containing compounds were added to the above solution (Y/Ti = 0.75 mol %) and ultrasonicated for another 15 min. The mixed solution and 2 mL of HF (40%) were transferred into a stainless steel autoclave lined with polytetrafluoroethylene (Teflon) (100 mL). Next, an FTO substrate (F:SnO$_2$, TEC 15, Shenzhen CSG Float Glass Co. Ltd.), which had been ultrasonically cleaned for 60 min in a mixed solution of deionized water, acetone, and 2-propanol with a volume ratio of 1:1:1, was leaned at an angle against the wall of the Teflon liner with the conducting side facing down. The solvothermal synthesis was conducted at 200 °C for 12 h in an electric oven. After the synthesis, the autoclave was then removed from the oven and left to cool naturally to room temperature. The FTO substrate was removed, rinsed extensively with deionized water and ethanol, and finally dried at 60 °C in an oven. Subsequently, the films were heated to 600 °C at a heating rate of 1 °C min$^{-1}$ and calcinated for 2 h to obtain a highly crystalline anatase phase.

**Characterizations.** The chemical composition of each solid sample was determined by X-ray fluorescence analysis (XRF) with a Philips PW2403 X-ray spectrometer (Philips, Holland). The concentrations of Y and Eu in each solution were analyzed by inductively coupled plasma-molic emission spectrometry (ICP-OES) with PerkinElmer’s Optima 8000 (PerkinElmer, America). The crystal structure was examined by X-ray diffraction (XRD) analysis with a Bruker axs D8 Advance using Cu Kα radiation (Bruker, Germany). The morphology of the samples was examined by SU-8020 field-emission scanning electron microscopy (SEM) (Hitachi, Japan) and JEM-2100F high-resolution transmission electron microscopy (TEM) (JEOL, Japan). X-ray photoelectron spectroscopy (XPS) data were obtained with an ESCALab220-XL electron spectrometer from VG Scientific using 300WAl KR radiation (E = 1486.6 eV) in a base pressure of $3 \times 10^{-9}$ mbar. The binding energies were referenced to the C 1s line at 284.8 eV from adventitious carbon. The photoluminescence–PL spectra were tested with a Jasco Shimadzu RF-5301PC fluorescence spectrophotometer using a 355 nm line from a xenon lamp. The diffuse reflectance spectra (DRS) were characterized by an UV–vis spectrophotometer (UV 2550, Shimadzu, Japan).

**Evaluation of Photocatalytic Activities.** The evaluation of photocatalytic activity of the samples for the photocatalytic removal of Cr(VI) and MO in aqueous solutions was performed at ambient...
temperature. \(K_2Cr_2O_7\) was used as the sources of Cr(VI). In the photocatalytic experiment, all the as-prepared films of 2.0 cm \(\times 4.0\) cm were used. Prior to the photocatalytic activity measurements, the as-prepared samples were cleaned with 0.1 M NaOH aqueous solution and rinsed extensively with deionized water, and then dried at 60 °C. A 30 W UV lamp with a maximum emission at about 365 nm was used as the illumination source. For comparison purpose, the photocatalytic experiment, all the as-prepared \(Y_2O_3/Eu_2O_3\) films were also conducted. \(P25\) TiO\(_2\) films were prepared by screen printing of \(P25\) TiO\(_2\) paste on the FTO substrate \(2.0 \text{ cm} \times 4.0 \text{ cm}\).23 The as-prepared \(P25\) TiO\(_2\) film was sintered at 500 °C for 30 min. For the photodegradation of aqueous MO, the films were immersed in 20 mL of the aqueous MO solution (10 mg/L) in a quartz cuvette. Prior to irradiation, all the films were dipped in a 20 mg/L MO solution for the saturated adsorption process. After irradiation for a given time, the concentration of MO in the resulted solution was analyzed by a Hitachi U-3900H spectrophotometer. The Lambert–Beer rule was applied using the characteristic absorbance band of the dye, 464 nm, to determine changes in concentration.

To evaluate the removal of Cr(VI) ions by photocatalyzed reduction, 20 mL of Cr(VI) solution with an initial concentration of 10 mg/L was circulated through a quartz tube. The pH value of the reaction suspension was adjusted to 2 using H\(_2\)SO\(_4\) or NaOH. Before irradiation, the samples were placed in the dark to establish adsorption/desorption equilibrium. After various irradiation intervals, 0.1 mL volumes of the solution were taken from the reaction vessel for the spectrophotometric method of the dye, 464 nm, to determine changes in concentration.

The photocatalytic stability of the Y-doped TiO\(_2\) nanosheets film was also tested. After the photocatalytic reactions, the catalyst films were soaked in 10% H\(_2\)SO\(_4\) solution for 12 h, subsequently washed with deionized water and ethanol several times and dried at 60 °C. After cleaning, the used Y-doped TiO\(_2\) nanosheets films were tested in fresh solutions of MO and Cr(VI) under the same experimental conditions as described above.

**RESULTS AND DISCUSSION**

**Waste Characterizations and Recycling.** The chemical compositions of CRT phosphor waste were analyzed by XRF. A large number of waste samples were studied, of which the common feature was a uniform composition. The phosphor waste is composed of SO\(_3\) (39.37 wt %), ZnO (33.42 wt %), Y\(_2\)O\(_3\) (16.79 wt %), Al\(_2\)O\(_3\) (6.43 wt %), SiO\(_2\) (1.86 wt %), and Eu\(_2\)O\(_3\) (1.07 wt %) as the main components (Table 1). The chemical analysis is in agreement with the XRD pattern recorded for CRT phosphor waste (Figure 1a). As shown in Figure 1a, the main crystalline phases in the waste samples are Y\(_2\)O\(_3-SiO_2\)-Eu\(^{3+}\) (JCPDS No. 24-1424), ZnS (JCPDS No. 77-2100), Ca\(_3\)Al\(_2\)P\(_2\)Si\(_2\)O\(_15\) (JCPDS No. 36-0108), and Al metal (JCPDS No. 85-1327). Figure S1 is a typical SEM image of CRT phosphor waste. It shows that CRT phosphor waste is a granular material composed of pseudopolyhedral particles with diameters ranging from 0.1 to 2.0 \(\mu\)m (Figure S1).

To evaluate the leaching of yttrium and europium, 50 g of CRT phosphor waste samples was leached with 1 L of sulfuric acid (3 mol/L) and 5 mL of H\(_2\)O\(_2\) for 2 h with stirring (300 rpm) at 50 °C. The leaching residue was also analyzed by XRF, as shown in Table 1, which confirmed that the yttrium and europium contents totally dissolved in the acid solution. Figure 1b shows the XRD patterns of the leaching residue. The diffraction peaks agree with those of ZnS (JCPDS No. 77-2100) and \(S_8\) (JCPDS No. 83-2285), whereas the Y\(_2\)O\(_3-SiO_2\)-Eu\(^{3+}\) peaks disappeared, confirming that yttrium and europium were completely leached out under these conditions. After leaching and filtering, the Y–Eu sulfate concentrate was obtained.

After the separation and purification of Y–Eu sulfate solutions by traditional ammonia precipitation, oxalate precipitation and calcination, a product of 99.74% pure Y\(_2\)O\(_3\)/Eu\(_2\)O\(_3\) mixtures was obtained, as shown in Figure 2a and Table 1. Next, the as-obtained Y\(_2\)O\(_3\)/Eu\(_2\)O\(_3\) mixtures were treated using a photochemical reduction method (Figure S2). After 72 h of UV light irradiation, 99% of the europium was recycled as EuSO\(_4\) with a purity of 97% (Figure 2b and Table S1). Finally, the yttrium-containing solutions were slowly evaporated at 70–80 °C to obtain yttrium sulfate. The as-obtained yttrium sulfate was used as a raw material to synthesize a Y-doped TiO\(_2\) photocatalysis material.

**Samples Preparation and Characterizations.** Morphologies and Structures. The other aim of this work was to synthesize low-cost Y-doped TiO\(_2\) nanosheets film on FTO substrate using recycled yttrium sulfate as a dopant source. We therefore performed a solvothermal treatment with Ti(OBu)\(_4\) in acetic acid, which was combined with the recycled yttrium sulfate and hydrofluoric acid mixture, and the cleaned FTO substrate was placed into the reaction mixture. The morphology and structure of the as-obtained Y-doped TiO\(_2\) nanosheets film were characterized by SEM and TEM as shown in Figure 3. A top view of the Y-doped TiO\(_2\) nanosheets film in Figure 3a reveals that numerous irregular-shaped nanosheets are uniformly and densely distributed on the FTO substrate with an average lateral size of 1.5 \(\mu\)m. Higher magnification of

**Figure 1.** XRD patterns of (a) CRT phosphor waste and (b) the leaching residue.
the sample (Figure 3b) displays that the TiO₂ nanosheets have a highly ordered arrangement with well-defined layer-by-layer structures, and the thickness of an individual nanosheet was approximately 20 nm. A cross-sectional view of the Y-doped TiO₂ film in Figure 3c shows that the film thickness is approximately 1.3 μm. Figure 3c also confirms that these nanosheets are composed of layer-by-layer structures.

Well-defined sheet-shaped TiO₂ structures are clearly observable in the TEM image in Figure 3d. Figure 3e shows a high-resolution TEM image recorded from Figure 3d, which evidently showed that the lattice spacing parallel to the top and bottom facets was 0.19 nm, agreeing well with the spacing of the (200) and (020) lattice planes of anatase type TiO₂.²⁴,²⁵ The same region of SAED patterns (Figure 3f) can be indexed into the diffraction spots of the [001] zone, indicating that the top and bottom surfaces of the TiO₂ nanosheets are high-energy {001} facets. The clear diffraction spots also indicate the single crystalline nature of the nanosheets (Figure 3f). These structural analyses indicate that the prepared Y-doped TiO₂ nanosheets are dominated by the {001} facets, and the corresponding percentage of exposed {001} facets is statistically estimated to be 97%. Energy dispersive analysis of X-rays (EDAX) analysis result confirms the presence of Y in the TiO₂ nanosheets film and the doping concentration of Y is low at approximately 0.3 wt % (Figure S3). These results confirmed that the Y-doped TiO₂ nanosheets film with dominant {001} facets was successfully synthesized by the proposed solvothermal method.

The typical XRD pattern of the as-synthesized Y-doped TiO₂ nanosheets film was measured (Figure 4). As depicted in Figure 4a, the as-synthesized sample showed peaks at 2θ values of 25.3°, 36.9°, 37.8°, 38.5°, 48.1°, 53.9°, 55.1°, 62.1°, and 62.7°, corresponding to the anatase (101), (103), (004), (112), (200), (105), (211), (213), and (204) crystal planes (JCPDS No. 21-1272), respectively. In addition, the peak of the (100) crystalline phase of hexagonal TiOF₂ (JCPDS No. 77-0132) was visible. After calcination at 600 °C for 2 h, the as-synthesized sample transformed into pure anatase TiO₂ phase with high crystallization (Figure 4b). The diffraction peaks of TiOF₂ completely disappeared, indicating that F ions in TiOF₂ are easily removed by the annealing treatment. No crystalline phase for the yttrium oxides was observed. This absence can possibly be attributed to the very small level as determined from the EDAX results and uniform dispersion of Y³⁺ ions in the TiO₂ nanocrystals, similar to reported behavior for La doping.²⁶,²⁷

The DRS spectra were used to evaluate the light absorption and band gap of as-prepared Y-doped TiO₂ samples, as shown in Figure S4. It can be clearly seen that a slight shift of the absorption profile was observed for Y-doped TiO₂ nanosheets,
compared with pure P25 TiO₂ (Figure S4a). For further study of the change gap of Y-doped TiO₂ nanosheets, the plots of \( F(R - E) \) vs. photon energy is shown in Figure S4b. It can be found that the band gap of TiO₂ was narrowed from 3.25 to 3.04 eV after Y-doped. The results show that the Y³+ ions doping reduced the band gap of TiO₂.

To confirm the surface composition and chemical states of the elements, the as-prepared anatase Y-doped TiO₂ nanosheets film were investigated by XPS (Figure 5). The O 1s peaks appearing at 529.9 and 531.5 eV were attributed to the lattice oxygen and the hydroxyl groups, respectively (Figure 5a). It has been reported that the hydroxyl groups can react with photoinduced holes to yield highly oxidizing surface-bound ·OH radicals. Additionally, the O 1s spectrum exhibited a third peak at approximately 532.8 eV corresponding to the Y–O bonds. The binding energies of Ti 2p₃/₂ and Ti 2p₁/₂ are approximately 458.7 and 464.5 eV (Figure 5b), respectively. The splitting difference of 5.8 eV between the two bands indicates that Ti was present as Ti⁴⁺ in the sample.

The two peaks of the Ti 2p energy levels in Y-doped TiO₂ nanosheets film are slightly shifted toward higher energies compared with the values of pure TiO₂ (Figure S5), implying that the yttrium ions may be incorporated into the TiO₂ lattice. The Y 3d₃/₂ and Y 3d₅/₂ peaks with binding energies at 160.1 and 157.9 eV, respectively, are in agreement with the Y–OH bond reported in the literature (Figure 5c).

To study the growth mechanism of the Y-doped TiO₂ nanosheets film with dominated highly reactive {001} facets, samples with different reaction times were investigated. Figure 6a–e shows typical SEM images of the as-synthesized Y-doped TiO₂ nanosheets film under different reaction times. It shows that only a thin layer of TiO₂ spherical nanoparticles and octahedral nanorods can be obtained on the FTO substrate with 1 h of crystallization (Figure 6a). With 3 h of growth time, sparse sheet-shaped TiO₂ structures were formed with a thickness of approximately 350 nm (Figure 6b). When the growth time was increased to 6 h, the sheet-shaped TiO₂ filled the FTO substrate, and the average thickness increased to 1.3 μm (Figure 6c). The higher magnification SEM image shown in the lower row in Figure 6c reveals that the sheet-shaped TiO₂ were eroded by exfoliation into a layer-by-layer nanosheets structure that appeared on the central parts of the plane crystal facets. This observed erosion by exfoliation phenomena may be due to HF etching or dissolution effect on TiO₂ {001} facets.

Further erosion by exfoliation on the sheet-shaped crystal facets was observed, and the thickness of the sheet-shaped structure was decreased to approximately 600 nm after 9 h of reaction (Figure 6d). After 12 h of growth, the sheet-shaped TiO₂ was completely eroded/exfoliated and replaced by irregular-shaped layer-by-layer nanosheets structure (Figure 6e). Moreover, the thickness of an individual nanosheet was also decreased to approximately 20 nm as shown in the higher magnification SEM image (lower row) in Figure 6e. On the basis of the experimental results, a proposed growth mechanism of the Y-doped TiO₂ nanosheets film with dominant {001} facets is given in Figure 6f. Initially, Ti(OBu)₄ reacted with acetic acid and formed TiO₂ nanoparticles according to the following reaction (eqs 1 and 2):

\[
\begin{align*}
\equiv & Ti - O - C₅H₉ + CH₃COOH \\
& \rightarrow \equiv Ti - OH + CH₂COC₄H₉ \\
\equiv & Ti - OH + HO - Ti≡ \rightarrow \equiv Ti - O - Ti≡ + H₂O
\end{align*}
\]

(1)

(2)

Then, these primary nanoparticles continuously grew along the [001] direction to form TiO₂ nanosheets in the presence of fluoride ions. However, it has been reported that TiO₂ {001} facets synthesized at a high HF concentration can also be seriously eroded by HF (eq 3):

\[
\text{TiF}_2 + 2HF \xrightarrow{\text{dissolution}} \text{TiF}_2\cdot\text{H}_2\text{O}
\]

(3)

Thus, in the continuing reaction, the crystal growth is slower than the HF etching/dissolution, the TiO₂ {001} facets are eroded by exfoliation, and the thickness of the nanosheets decreases to form layer-by-layer nanosheets structures.

**Evaluation of Photocatalytic Activities.** Dye effluents from textile industries are becoming a serious environmental problem, as they are stable in light and resistant to chemical and biological degradation. In addition, hexavalent chromium (Cr(VI)) contamination in groundwater is a global environmental problem that poses a health risk to humans because of its high acute toxicity and carcinogenic activity. Photocatalysis through TiO₂...
in the presence of nanostructured TiO$_2$ has been proven to be effective for the removal of various harmful pollutants.\textsuperscript{3} Therefore, the photocatalytic efficiency of MO and Cr(VI) was evaluated using the as-prepared Y-doped TiO$_2$ nanosheets film under the UV irradiation of a 30 W high-pressure Hg lamp. For comparison purpose, the photocatalytic oxidation of MO and reduction of Cr(VI) by P25 TiO$_2$ (a benchmark photocatalyst for photocatalytic activity evaluation) was also conducted, as shown in Figure 7. Figure 7a,c shows the photocatalytic oxidation of MO and the reduction of Cr(VI) under UV light irradiation in the presence and absence of the photocatalysts, respective. Blank experiments suggested that the concentration changes of MO and Cr(VI) under UV light irradiation without the photocatalyst could be ignored (curve 1 in Figure 7a,c). Significantly,
the Y-doped TiO₂ nanosheets film with dominant {001} facets (curve 3 in Figure 7a,c) exhibit a higher photocatalytic activity than P25 TiO₂ (curve 2 in Figure 7a,c) both in the MO system or the Cr(VI) system. For example, after UV irradiation for 360 min, 82.8% of MO is photodegraded on the Y-doped TiO₂ nanosheets film, compared with a 59.3% reduction by P25 TiO₂. And after 300 min of UV light irradiation, the Cr(VI) removal was 96%, compared with a 71.5% reduction by P25 TiO₂.

The absorption spectrum of MO in the presence of the Y-doped TiO₂ nanosheets film under exposure to UV light for various durations in the photocatalytic degradation process was also shown in Figure S6. It can be seen that the absorption peak at \( \lambda = 464 \text{ nm} \) diminishes gradually as the exposure time increases and no new absorption bands appear in either the visible light or the UV region. This indicates the complete degradation of MO by photocatalyzed reactions.

To compare quantitatively the photocatalytic activities, the apparent rate constant \( (k_{\text{app}}) \) for photocatalytic oxidation of MO and reduction of Cr(VI) over the film samples was evaluated using a pseudo-first-order model (eq 4),34 as shown in Figure 7b,d:

\[
\ln\left(\frac{C_0}{C_t}\right) = k_{\text{app}}t
\]

where \( k_{\text{app}} \) is the apparent rate constant, \( C_t \) is the solution-phase concentration of dye, and \( C_0 \) is the initial concentration at \( t = 0 \). The apparent rate constant \( k_{\text{app}} \) values are also listed in Table 2.

**Table 2. Reaction Constant \( k_{\text{app}} \) (min⁻¹) in the MO and Cr(VI) with Various TiO₂ Samples**

In the MO system, the Y-doped TiO₂ nanosheets film with dominant {001} facets show the higher photocatalytic activity with a rate constant of \( 5.11 \times 10^{-3} \text{ min}^{-1} \), which is larger than that of P25 TiO₂ \( (2.45 \times 10^{-3} \text{ min}^{-1}) \) by a factor of 2.09. In the Cr(VI) system, the calculate rate constant for P25 TiO₂, is \( 3.89 \times 10^{-3} \text{ min}^{-1} \). In strong contrast, the rate constant of \( 1.03 \times 10^{-2} \text{ min}^{-1} \) is obtained from Y-doped TiO₂ nanosheets film, almost three times larger than that of P25 TiO₂.

The photocatalytic oxidation of MO and reduction of Cr(VI) was cycled 7 times under the same conditions used to investigate the stability of the Y-doped TiO₂ nanosheets film, as shown in Figure S7. No obviously deactivation was observed in the cycling tests for the photoreduction of MO and Cr(VI) on the Y-doped TiO₂ nanosheets film, indicating that it possesses outstanding photocatalytic stability.

**Proposed Mechanism.** The possible mechanism is proposed in Figure 8, which shows the possible reactions in the photocatalysis process. Figure 8a shows the proposed reactions in the photocatalytic oxidation of MO on the Y-doped TiO₂ nanosheets under UV light irradiation. The whole reaction mechanism starts with the electron–hole pair created in TiO₂ under UV light irradiation (eq 5).

\[
\text{TiO}_2 + h\nu \rightarrow h^+ + e^-(5)
\]

The separation efficiency of photogenerated electron–hole pairs determines photocatalytic properties. It has been known that TiO₂ modification with lanthanides ions yield excellent electrons scavenging capacity.36,37 Thus, we used the PL technique to define the separation capacity of photogenerated electrons and holes. Figure S8 illustrates the room-temperature PL spectra of the as-obtained Y-doped TiO₂ and pure P25 TiO₂ samples under the excitation wavelength of 355 nm. Compared with the pure P25 TiO₂, the Y-doped TiO₂ samples obviously exhibit lower intensity of emission spectrum, which clearly indicates that a more efficient transfer and separation of photogenerated electrons and holes caused by doped Y³⁺ ions. Therefore, the photogenerated electrons are quickly trapped by the Y³⁺ ions in Y-doped TiO₂ system (eq 6), resulting in the formation of Y²⁺.36 The unstable Y²⁺ ions may also react with adsorbed O₂ to thus forming highly reactive superoxide ions (O₂⁻) (eq 7).

\[
\begin{align*}
\text{Y}^{3+} + e^- & \rightarrow \text{Y}^{2+} \\
\text{Y}^{2+} + \text{O}_2 & \rightarrow \text{Y}^{2+} + \text{O}_2^- \\
\end{align*}
\]

Through a series of redox reactions, a number of charged species and radicals with high redox potentials are generated (eqs 8–10).

\[
\begin{align*}
\text{O}_2^- + \text{H}^+ & \rightarrow \cdot \text{OOH} \\
2 \cdot \text{OOH} & \rightarrow \text{O}_2 + \text{H}_2\text{O}_2 \\
\text{H}_2\text{O}_2 + e^- & \rightarrow \cdot \text{OH} \\
\end{align*}
\]
In addition, it has been widely reported that surface O molecules on the {001} facets are unstable and very reactive, which leads to more oxygen vacancies on the exposed {001} facets.37 The defects caused by these oxygen vacancies can provide sites for the photogenerated holes to react with dissociated water molecules and hydroxyl groups, thus forming ·OH radicals (eqs 11 and 12):

\[
\text{h}^+ + \text{H}_2\text{O} \rightarrow \cdot\text{OH} + \text{H}^+ \quad (11)
\]

\[
\text{h}^+ + (-\text{OH}) \rightarrow \cdot\text{OH} \quad (12)
\]

As a result, these highly oxidizing species can be strongly reactive with organic molecules to produce degradation products (eqs 13 and 14).

\[
\text{O}_2^- + \text{MO} \rightarrow \text{degradation of products} \quad (13)
\]

\[
\cdot\text{OH} + \text{MO} \rightarrow \text{degradation of products} \quad (14)
\]

Figure 8b shows the possible reactions in the photocatalytic reduction of Cr(VI) on the Y-doped TiO\textsubscript{2} nanosheets under UV light irradiation. For the removal of Cr(VI) in the reaction systems, first, TiO\textsubscript{2} nanosheets were excited to generate electron–hole pairs (eq 5). Then, the photogenerated electrons can directly reduce adsorbed Cr(VI) to Cr(III) according to eq 15.36 In the Y-doped TiO\textsubscript{2} nanosheets, the Y\textsuperscript{3+} ions are reduced to Y\textsuperscript{2+} by the photoelectrons from TiO\textsubscript{2} nanosheets according to eq 6.36 Then, the unstable Y\textsuperscript{2+} ions can easily reduce Cr(VI) to Cr(III) according to eq 16. Adsorbed H\textsubscript{2}O or hydroxyl groups accepted holes in eqs 7 and 8), thus forming ·OH radicals, and the photocatalysis redox cycle thereby continued, resulting in an enhanced Cr(VI) removal capacity in the Y-doped TiO\textsubscript{2} nanosheets.

\[
3\text{e}^- + \text{Cr(VI)} \rightarrow \text{Cr(III)} \quad (15)
\]

\[
3\text{Y}^{2+} + \text{Cr(VI)} \rightarrow 3\text{Y}^{3+} + \text{Cr(III)} \quad (16)
\]

With the purpose of understanding the role of the those active species during the photodegradation of MO over Y-doped TiO\textsubscript{2} nanosheets film, ammonium oxalate (AO, 1 mM), benzoquinone (BQ, 1 mM) and isopropyl alcohol (IPA, 1 mM) were used as scavenging reagents for h\textsuperscript{+}, O\textsubscript{2}\textsuperscript{−}, and ·OH, respectively.39,40 Figure 9a,b displays the photocatalytic activities of MO over Y-doped TiO\textsubscript{2} nanosheets film under different scavengers. The addition of BQ can reduce the photocatalytic efficiency of MO to the largest extent, indicating that O\textsubscript{2}\textsuperscript{−} can be generated by photoelectrons reacting with adsorbed O\textsubscript{2} and served as the main active species during the photodegradation process. When added IPA and AO into the MO system, the photocatalytic activities of MO decreased to some degree, suggesting that the h\textsuperscript{+} and ·OH radicals contribute almost equally and moderately during the photodegradation process. However, the results also show that the h\textsuperscript{+} contribute a less extent than ·OH radicals. Thus, it can be concluded that the reaction (eqs 8–10) may occur to generate more ·OH radicals during the photocatalytic process.

### CONCLUSIONS

In summary, CRT waste is right with yttrium oxide and europium oxide, which makes this waste useful for recovering high-value REEs. Moreover, these recycled REEs are useful to prepare low-cost sustainable photocatalytic materials. In this work, we have successfully prepared Y-doped anatase TiO\textsubscript{2} nanosheets film with exposed {001} facets using cheap recycled yttrium as a dopant source, which was derived from CRT phosphor waste. The as-prepared Y-doped TiO\textsubscript{2} nanosheets film exhibit a layer-by-layer self-assembled structure. Observation by TEM and SEM confirmed the TiO\textsubscript{2} nanosheets with dominant {001} facets, and the percentage of these facets was statistically estimated to be 97%. The presence of the element Y in TiO\textsubscript{2} nanosheets film was verified by EDAX and XPS analyses. A possible growth mechanism was postulated by systematically investigating the influence of the reaction time. The formation of layer-by-layer TiO\textsubscript{2} nanosheets structure could be due to an etching/dissolution process under a high HF concentration. Remarkably, the Y-doped TiO\textsubscript{2} nanosheets film exhibit higher photocatalytic efficiency compared with P25 TiO\textsubscript{2} for both oxidation of MO and reduction of Cr(VI). The remarkably improved photocatalytic activity of the Y-doped TiO\textsubscript{2} nanosheets film may be due to the synergistic effect of the efficient separation and transfer of the photogenerated e\textsuperscript{−}/h\textsuperscript{+} pairs due to the presence of the Y\textsuperscript{3+}/Y\textsuperscript{2+} redox couple and the high percentage of exposed {001} facets. Furthermore, Y-doped TiO\textsubscript{2} nanosheets film possesses outstanding photocatalytic stability, showing great potential in the detoxification of harmful pollutants in wastewaters. We hope that this work will not only enrich the recycling methods of CRT phosphor waste but also provide a new means to prepare low-cost sustainable photocatalytic materials using economically viable waste with promising applications in both energy and environmental fields.
